

PROJECT PHASE 4

Ayyub Shaffy (am12321), Matija Susic (ms14012)

1. Architecture and Design

High-Level Structure

In Phase 4, we upgraded the multi-threaded server to simulate a **Single-CPU Scheduler**. While the server still spawns a thread for every connected client to handle network I/O, the actual execution of commands is now serialized to simulate a single processor environment.

We implemented a **Centralized Scheduler Architecture**:

- **Client Threads:** Handle communication and parsing, but they do not execute commands immediately. Instead, they package requests into Job structs and add them to a waiting queue.
- **Scheduler Thread:** A dedicated thread that manages the queue, selects the next job based on the SRJF+RR algorithm, and grants the "CPU" (permission to execute) to a specific client thread.

The file structure was updated:

- **scheduler.c / scheduler.h:** New files containing the Job struct definition, the priority queue linked list, and the core scheduling logic (SRJF, preemption checks, and timeline generation).
- **server.c:** Refactored to launch the `scheduler_thread_func` on startup. The `client_thread_func` was modified to use Condition Variables to wait for execution turns instead of running immediately.
- **demo.c:** A helper program created to simulate long-running processes for testing time-slicing.

Key Design Decisions

1. The Centralized Scheduler Thread We created a dedicated thread (`scheduler_thread_func`) that runs an infinite loop, monitoring the job queue.

- **Reason:** This separates the *decision-making* (who runs next?) from the *execution* (running the process). It simplifies synchronization by having a single authority on the system's state.

2. Condition Variables for Flow Control Each Job struct contains its own `pthread_cond_t`. When a client thread submits a job, it sleeps on this condition variable. The scheduler signals this specific variable when it is that job's turn.

- **Reason:** This avoids "busy waiting" (CPU polling). Client threads consume zero CPU resources while waiting in the queue, perfectly simulating a waiting process state.

3. Process Control via Signals (SIGSTOP/SIGCONT) For program commands (like ./demo), we do not kill and restart the process when time runs out. Instead, we use kill(pid, SIGSTOP) to pause it and kill(pid, SIGCONT) to resume it.

- **Reason:** This is required to maintain the state of the process. Restarting demo from the beginning every time would violate the requirement to resume execution from where it left off.

4. Hybrid Scheduling Logic We implemented a prioritized selection logic. "Shell Commands" (e.g., ls, pwd) are assigned a burst time of -1 and treated as non-preemptive high-priority tasks. "Program Commands" (e.g., ./demo, ./hello) are preemptive and follow Shortest Remaining Job First (SRJF).

- **Reason:** This ensures the UI remains responsive (instant shell output) even when heavy computation (long demo jobs) is happening in the background.

Data Structures

The Job Struct We introduced a Job struct to track the execution state of a client request:

```
typedef struct Job {  
  
    int id;                // Client ID  
  
    int socket_fd;         // Connection to client  
  
    bool is_shell_cmd;     // Priority flag  
  
    int total_time;        // Predicted burst  
  
    int remaining_time;    // For SRJF  
  
    pid_t pid;             // Child process ID (for SIGSTOP/CONT)  
  
    int pipe_fd;           // To read output chunks  
  
    bool started;          // Has fork() happened yet?  
  
    int rounds_run;        // To calculate Quantum (3s vs 7s)  
  
    // Synchronization  
  
    pthread_cond_t cond;   // Thread sleeps here
```

```
bool my_turn;           // Flag to wake up

struct Job *next;       // Queue link

} Job;
```

2. Implementation Highlights

Core Flow

1. **Submission:** When a client sends a command, `client_thread_func` creates a `Job`, calculates the predicted burst (N for demo, -1 for shell), and calls `add_job()`.
2. **Wait:** The client thread locks the `sched_lock` and waits on `pthread_cond_wait(&j.cond)`.
3. **Selection:** The `scheduler_thread_func` wakes up, scans the linked list using `get_next_job()`, and signals the chosen job.
4. **Execution:** The client thread wakes up, executes for a specific **Quantum**, and then yields the CPU back to the scheduler.

Scheduling Algorithm (Combined SRJF + RR)

Our `get_next_job` function implements the logic:

1. **Shell Commands First:** It scans the list for any job with `is_shell_cmd == true`. These are run immediately (FCFS among themselves).
2. **SRJF for Programs:** If no shell commands exist, it finds the job with the minimum `remaining_time`.
3. **Anti-Monopoly Rule:** We implemented the check: `if (count > 1 && curr->id == last_job_id) skip`. This ensures that if multiple jobs are available, the same job is not selected twice in a row (unless it's the only one left).

Variable Quantum and Preemption

- **Variable Quantum:** Inside `client_thread_func`, we check `rounds_run`. If it is 0, we set `quantum = 3`. For all subsequent rounds, `quantum = 7`.
- **Preemption:** Inside `add_job`, if a new job arrives that has a shorter remaining time than the *currently running* job, we set `current_job->preempt_requested = 1`.
- **Interrupt Loop:** The execution loop reads output from the child process line-by-line. After every line (simulating 1 second), it checks `preempt_requested`. If true, it stops execution early, saving the state for the next round.

Timeline Generation

To verify correctness, we implemented a linked list `TimelineEntry`. Every time a job finishes a slice, `append_timeline()` records the job ID and duration. When the queue becomes empty, `print_timeline()` dumps the Gantt chart string (e.g., `0-P6-(3)-P7-(6)...`) to the server console.

3. Execution Instructions

1. **Compile:** Run `make` in the project directory. This compiles server, client, and demo.

```
make
```

2. **Start Server:**

```
./server
```

3. **Run clients:** Open multiple *new* terminal windows. In each one, you can connect to the server.

```
# In Terminal 2
./client
```

```
# In Terminal 3
./client
```

4. **Run Tests:**

- Shell commands: `ls`, `pwd`

- Demo programs: ./demo 12, ./demo 5

4. Testing

We validated the system using the three scenarios described in the project requirements. Please zoom in to the screenshots for more detail.

Test Scenario 1

```

ms14012@OCLAP-V1525-CSD:~/CS-UH-3010-Opearting-Systems-Project/Phase_4$ ./server

3 concurrent clients: each client running the demo program with different values of N

5. Challenges

1. Handling Preemption Smoothly

One of the toughest parts was figuring out how to pause a running process without killing it. At first we tried just waiting, but that ended up blocking the whole scheduler.

Fix: We switched to using `pipe()` so we could read the child's output one line at a time and check for preemption between lines. We also used `SIGSTOP` to pause the child cleanly so it didn't lose any progress.

2. Enforcing a Single-CPU Abstraction

At one point, multiple jobs were effectively running at the same time, even though the project assumes a single CPU. When we unlocked the global scheduler mutex around `execute_demo`, the scheduler started handing the CPU to a second job while the first child process was still running.

Fix: We introduced a global `cpu_busy` flag and a `current_job` pointer, both protected by the scheduler mutex. The scheduler only picks a new job when `!cpu_busy`, and the client thread explicitly sets `cpu_busy = false` when its quantum ends or the job finishes. This kept the simulation logically single-core even though the implementation uses multiple threads.

3. Getting True SRJF Preemption (Not Just Time-Quantum Switching)

Initially, jobs only switched at the end of a time quantum. Even if a shorter job or a shell command arrived, the running program would finish its entire quantum before yielding, which violated the “shortest remaining job first” and “shell commands preempt everything” requirements.

Fix: We added a `preempt_requested` flag on the running job and made `execute_demo_job` cooperative: it reads one line at a time from the child's pipe and checks `preempt_requested` between lines. When a new job is enqueued, `add_job` compares remaining burst times (or detects a shell command) and sets `current_job->preempt_requested = 1` if preemption is needed. This allows immediate preemption at the next line boundary rather than only at quantum expiry.

6. Division of Tasks

Ayyub: Implemented the `scheduler.c` core logic, including the `Job` struct, the linked list queue, and the `get_next_job` algorithm (SRJF + RR). Handled the mutex/condition variable synchronization between the scheduler and client threads.

Matija: Implemented the process control logic (`fork`, `exec`, `SIGSTOP`, `SIGCONT`) and the variable quantum logic inside `server.c`. Wrote `demo.c` and the timeline generation/printing functions. Wrote the report.

7. References

Linux Programmer's Manual (man pages): `sigaction`, `kill`, `pthread_cond_wait`.
